Abstract The aim of this work was to improve existing transformation protocols and to transform specific genotypes of *Paspalum notatum* (bahiagrass) for functional analyses of candidate genes involved in reproduction. Three different explants were assayed for *in vitro* plant regeneration: mature seeds, mature embryos, and shoot meristems. Plant regeneration was achieved with all explant types, but mature seeds produced the optimal rate (78.0%) and were easiest to manipulate. A method based on serial re-induction of calli from meristems of the regenerated lines was also developed, which could be useful in plant breeding strategies pursuing somaclonal variation. Transient transformation experiments were performed on calli obtained from mature seeds using a compressed helium gene gun. Transient transformation constructs included anthocyanin-synthesis genes cloned under the CAMV 35S promoter and an enhanced green fluorescent protein gene (*egfp*) driven by the rice actin1 (*act1*) promoter. Selection curves for ammonium glufosinate were developed in order to determine the optimal selective pressure for stable transformation (1.0 mg/L). Stable co-transformation experiments were carried out with two different constructs containing: (1) the reporter *egfp* gene cloned under the rice *act1* promoter and (2) the selector *bar* gene driven by the ubiquitin promoter. A total of 27 (64.2%) transgenic plants out of 42 resistant plants analyzed were obtained. The presence of the transgenes in regenerated plants was confirmed by

polymerase chain reaction and DNA gel blot analysis. Gene expression was demonstrated by eGFP fluorescence detection and *in vivo* assays for ammonium glufosinate tolerance. This platform is being used to generate transgenic plants of *P. notatum* to analyze the function of apomixis-associated candidate genes.

Keywords Biolistic transformation · *Paspalum notatum* · Ammonium glufosinate · *Egfp* · Apomixis

Introduction

Apomixis is a genetically determined type of asexual reproduction in angiosperms that results in the production of viable seed from maternal tissues in the absence of meiosis and fertilization (Nogler 1984). The offspring originating from apomixis are exact genetic replicas of the mother plants. This trait is perceived as an important potential tool for plant breeding, since its manipulation would enable preservation of hybrid vigor and simplify plant breeding methods and wide-crossing (Spillane *et al.* 2004). Apomixis, however, is absent from major crops. To date, plant genetic transformation has not been explored as a tool to facilitate harnessing apomixis for the benefit of agriculture. While in the past few years dozens of genes differentially expressed during sexual and apomictic development (Leblanc *et al.* 1997; Chen *et al.* 1999; Albertini *et al.* 2004; Cervigni *et al.* 2008; Laspina *et al.* 2008) or positionally linked to apomixis (Calderini *et al.* 2006; Conner *et al.* 2008; Podio *et al.* 2012) have been identified, functional studies have been performed only on randomly generated mutants originated from model sexual species.

Our research team identified 65 candidate genes differentially expressed in the reproductive tissues of sexual and apomictic *Paspalum notatum* (Laspina *et al.* 2008). Therefore, we are interested in developing an efficient transformation

protocol for introducing candidate genes in specific obligate apomictic or fully sexual tetraploid *P. notatum* genotypes to analyze the derived phenotypes.

Some useful *in vitro* culture and biolistic transformation protocols have already been developed for *P. notatum*. Bovo and Mroginski (1989) regenerated plants from tetraploid mature embryos. Marousky and West (1990) used mature caryopses as explants, whereas Shatters *et al.* (1994) employed leaf-stem cross-sections to initiate the plant regeneration process. Grando *et al.* (2002) used seeds from diploid *P. notatum* as explants, optimized the production of embryogenic calli and showed they were amenable to transient transformation. Altpeter and Positano (2005) developed an efficient protocol for the regeneration of tetraploid bahiagrass plants from callus using mature seed explants. Smith *et al.* (2002) obtained tetraploid transgenic plants resistant to glufosinate, and Gondo *et al.* (2005) produced bialaphos-resistant diploid plants through callus bombardment. Altpeter and James (2005) used biolistic gene transfer into embryogenic callus derived from mature seeds to obtain paromomycin-resistant apomictic bahiagrass. Altpeter's group utilized this protocol to produce transgenic plants displaying reduced levels of endogenous gibberellins (Agharkar *et al.* 2007), and to study *bar* transgene expression in apomictic progeny of bahiagrass (Sandhu *et al.* 2007). In addition, the expression of *Arabidopsis ATHB16* (Zhang *et al.* 2007) and wild barley *HsDREB1A* (James *et al.* 2008) transcription factors in bahiagrass originated changes in plant architecture and abiotic stress tolerance, respectively. Sandhu and Altpeter (2008) used two minimal transgene expression constructs and evaluated co-integration, quantified coexpression, and analyzed inheritance to apomictic seed progeny. More recently, Xiong *et al.* (2009) obtained drought tolerant plants by over-expressing the barley *WRKY38* transcription factor. All these studies were conducted on the apomictic, tetraploid cultivar 'Argentine' aiming at the molecular improvement of turf quality.

We considered all of these previously developed methodologies as valuable starting points and analyzed several independent protocols, examining alternative explants and conditions, to design a platform best suited to a wide range of genotypes. Genetic improvement of tetraploid *P. notatum* cultivars has been compromised by the absence of genetic recombination in natural apomictic genotypes. Genetic manipulation through cellular and molecular techniques may overcome this difficulty. The aim of this work was to improve on existing transformation protocols and to transform specific genotypes of *P. notatum* for gene functional analyses. Moreover, we developed a serial meristem-based *in vitro* culture approach, derived from the protocol reported by Bajaj *et al.* (2006), consisting of two successive rounds of embryogenic calli induction from meristematic tissues, which possibly leads to an accumulation of mutations. This novel strategy could be implemented for *in vitro* culture-based plant breeding

programs of apomictic grasses that ultimately seek the occurrence of somaclonal variation to generate novel genotypes. The tools developed here will be useful for apomixis research and breeding of clonally reproducing grasses.

Materials and Methods

Plant material. Experiments were conducted using *P. notatum* seeds obtained from: (1) the pseudogamous self-fertile tetraploid apomictic plant Q4117 ($2n=4x=40$) and (2) the completely sexual Q4188 ($2n=4x=40$) genotype, which was used as female parent in crosses to sexual JS-83 ($2n=4x=40$).

Q4117 is an obligate apomictic tetraploid clone collected from a natural population in southern Brazil (Ortiz *et al.* 1997). Q4188 is a hybrid derived from the cross between Q3664 and the natural apomict Q3853 (Quarin *et al.* 2003). JS-83 is an F_1 progeny obtained by crossing Q4188 as the female parent with Q4117 as a pollen donor (Stein *et al.* 2007).

***In vitro* culture media.** The media used in *in vitro* culture experiments are listed in Table 1. All media contained 4.3 g/L MS salts and B5 vitamins, 30 g/L sucrose, 2.2 g/L Phytigel™, and 100 μ L/L preservative solution (20% [v/v] Kathon CG [Sigma-Aldrich, Buchs, Switzerland], 140 mM potassium sorbate, and 140 mM sodium benzoate) to prevent contamination (Guri *et al.* 1998). Prior to solidification, the pH was adjusted to 5.7 with 1 N NaOH. Media were autoclaved for 30 min at 120°C and 150 kPa. Plant growth regulators (PGRs) and vitamins were sterilized using 0.2- μ m filters (Millipore, Billerica, MA) and added to temperate sterilized media.

Plant regeneration. The methodology used was based on protocols reported by Grando *et al.* (2002), Smith *et al.* (2002), and Gondo *et al.* (2005), with some modifications. Briefly, mature seeds originating from Q4117 (apomictic) or the cross Q4188×JS-83 (sexual) were incubated at 28°C for 48 h. Then, they were treated with concentrated H_2SO_4 for 30 min, for dehusking and dormancy breaking. The seeds were surface-sterilized with commercial bleach containing 50% (v/v) NaClO (35 g/L active chlorine) and 100 μ L Tween® 20 for 7 min, followed by a treatment with 97% (v/v) ethanol for 7 min. Finally, the seeds were washed three times with sterile distilled water and blotted dry on sterile filter paper.

For the mature seed-based regeneration protocol, approximately 15–30 seeds were placed in each Petri dish containing MM5 medium (Table 1) and cultured in the dark at 28°C for approximately 10 d. Each experiment carried out with seeds originating from plant Q4117 involved 12 plates and was repeated ten times (comprising a total of 120 plates). Each experiment carried out with seeds originated from the cross

Q4188 x JS-83 involved five plates and was repeated three times (comprising a total of 15 plates).

The mature embryo-based regeneration protocol was based on protocols reported by Bovo and Mroginski (1989) and Grando *et al.* (2002), with modifications. Sterilized Q4117 seeds were placed in sterile distilled water for a period of 1–24 h to soften the surface and facilitate embryo isolation. The seeds were scrutinized with a magnifying glass, and embryos were isolated with the help of a scalpel and tweezers. To evaluate the effect of the different PGRs and their concentrations, embryos were cultured in different media (MM5, MICE1, MICE2, and MICE3) to induce callus development (Table 1). Ten to twelve embryos were placed on each of four plates. One to eight experiments were carried out, depending on the media used. The embryos were placed on the plates always with the scutellum-side facing up. They were incubated in a chamber at 28°C with a photoperiod of 16-h light/d.

The methodology used to produce calli from meristems was based on the protocol reported by Bajaj *et al.* (2006), with modifications. Briefly, mature seeds originating from Q4117 were incubated at 28°C for 48 h. Finally, the seeds were washed three times with sterile distilled water and blotted dry on sterile filter paper. Twenty-five seeds were placed in each Petri dish (a total of 30 plates) containing IM media (Table 1) and maintained in the dark at 28°C for approximately 7 d. Those plates showing germinated seeds were exposed to light for 2 d with a photoperiod of 16-h light/d.

Meristematic regions from approximately 1 cm just above the mesocotyl region were excised. Cuttings were divided longitudinally into two pieces, placed face down on different callus induction media, MM1, MM2, MM3, MM4, MM5, and MM6 (Table 1), and maintained at 28°C in the dark.

Once compact, nodular, white-yellow calli were obtained using any of the explants (mature seeds, mature embryos, or meristem sections), fractions of about 5 mm were transferred to the same media every 2 wk. After 4–5 wk, sections of about 5 mm diameter were transferred to regeneration media (MRV1 or MRV2) to induce shoot development (Table 1). Calli were incubated at 28°C in a culture chamber with a photoperiod of 16-h light/d, or in the dark. Calli with shoots longer than 5 cm were then transferred to flasks containing rooting medium (MEEV1 or MEEV2) and incubated at 28°C in a culture chamber with a photoperiod of 16-h light/d (Table 1). Data collection was performed weekly along every step of the procedure.

Seedlings showing root development were washed with distilled water to eliminate the remnants of the culture media, transferred to pots with a 1:1 soil/vermiculite mix, maintained for 1 wk in high-humidity conditions in a growth chamber and placed in the glasshouse, which was set to operate at a maximum/minimum temperature of 35/15°C. The Kruskal-Wallis test was used to check the significance of the observed differential efficiency among seed batches and genotypes with a confidence interval of 95% using Statistical Procedures for

Agricultural Research ('agricolae') package for the R software (Mendiburu 2013).

Ammonium glufosinate selection curve. Sterilized mature seeds originating from genotype Q4117 were placed on MM5 medium for 5 wk. Calli were then cut into sections of about 5 mm diameter and sub-cultured in the same medium with ammonium glufosinate as a selective agent at different concentrations (0.5, 1.0, or 2.0 mg/L). Ammonium glufosinate solutions were sterilized by filtration with 0.2 µm Millipore filters and added to the temperate autoclaved media. After a period of 2 wk, calli were transferred to MRV1 medium with or without the addition of the selective agent. Then, they were divided into two groups, one of which was subjected to regeneration in the presence of the selective agent and the other in the absence of it. Selection conditions were the same as those applied in the first sub-culture. After 6 wk, calli subjected to selection that presented good shoot development (longer than 2 cm) were transferred to MEEV1 medium with or without the selection agent, but calli originating from unselected sub-cultures were maintained without selection. Regeneration controls consisted of calli treated with the same protocol but without addition of the selection agent. All calli were sub-cultured every 10 d to maintain constant selective agent concentrations. The number of calli with shoots or shoots and roots was analyzed for each of the selective conditions and referred to as the initial number of calli. Results were compared to determine the best selection conditions using the Kruskal–Wallis test using the *agricolae* package for the R software (Mendiburu 2013).

Transient reporter gene expression assay. We developed a protocol based on previous reports by Smith *et al.* (2002), Altpeter and James (2005), and Gondo *et al.* (2005), with modifications aimed at increasing transformation rates in our target genotypes. Sectors of 3-wk-old calli (with a 2 mm maximum diameter) originating from mature seeds of genotype Q4117 were used for bombardment. Prior to bombardment, 15 calli fragments were placed on sterile filter paper discs in the center of each Petri dish containing IM medium (Table 1) plus 0.4 M sorbitol and incubated at room temperature for 4 h. Vectors used for transient transformation were the plasmid pDP687, including two genes that regulate anthocyanin pigments synthesis under the control of the constitutive *Cauliflower mosaic virus* (CaMV) 35S promoter plus the first intron of an alcohol dehydrogenase gene (Ludwig *et al.* 1990), or the plasmid pAct1-gfbsd2, containing an enhanced green fluorescent protein gene (*egfp*) driven by the rice act1 promoter (Ochiai-Fukuda *et al.* 2006). Cells transformed with the pDP687 plasmid developed a purple pigmentation due to the generation of anthocyanin flavonoids. Cells transformed with *egfp* displayed a green fluorescent signal, which was detected with a fluorescence microscope (Nikon, Eclipse E200; Nikon, Surrey, UK). Plasmids used for transformation were

precipitated on tungsten particles (1 µm diameter), as follows: 60 mg of particles were placed in a 2 mL tube and washed with 1 mL isopropanol for 5 min, with gentle constant shaking. They were then sonicated for 1 min for resuspension and centrifuged for 3 min at 4,000×g. The supernatant was discarded, and the particles were resuspended in 1 mL sterile distilled water with vigorous shaking to improve the washing. Subsequently, the particles were centrifuged for 3 min at 4,000×g, and the supernatant was removed. This washing procedure was repeated twice. Finally, the particles were resuspended in 1.2 mL of sterile distilled water to obtain a stock 50 µg/µL suspension. This preparation was stored in a –20°C freezer. Once the particles were prepared, the plasmids were precipitated on them as follows: to a 1.5 mL Eppendorf tube, 65 µL of particle suspension, 6.5 µL plasmid DNA (1 µg/µL), and 75 µL 1 M Ca(NO₃)₂ pH 10 were added. The suspension was allowed to sediment, incubated on ice for 10 min, and then was briefly centrifuged to discard the supernatant. Finally, the particles were washed with 100 µL 70% (v/v) isopropanol. The pellet was resuspended in 65 µL isopropanol, with brief sonication to break up any clumps. The suspensions obtained using this protocol contained 50 µg particles/µL and 2 µg DNA/mg particles. The same volume of sterile distilled water was used instead of plasmid DNA for controls. Fifteen microliters of the particle suspension were placed in the middle of flying membranes, previously washed with 70% (v/v) isopropanol, which were allowed to dry in a horizontal position. A Biomics gene gun (Biomics, Brasilia, Brazil) was used for these experiments. Three compressed helium-generated alternative pressures were applied: 600, 800, and 1,100 psi, at a microprojectile flight distance of 5 cm. After bombardment, the calli were transferred to the same osmotic medium (IM+0.4 M sorbitol) for an additional hour. They were then moved to IM medium for 24 h and finally placed on callus induction medium. The calli were examined 48 h after transformation. Positive transformation events were visualized as dots on the callus surface that were purple due to the presence of anthocyanins or fluorescent due to the presence of eGFP. Data were statistically processed using the Minitab 15® Proof Version.

Stable transformation. Stable transformation experiments were performed using a protocol similar to that described above, but bombardments were carried out with equal amounts of plasmids pAct1-gfbsd2 (Ochiai-Fukuda *et al.* 2006) and pBS86-46 (Pact1D:cgf-s:rga2i:cgf-as:T35s/Pubi:bar:Tnos; Thompson *et al.* 1987). Stable transformation was performed using a protocol similar to that described for the transient transformation. After bombardment, the calli were placed in osmotic medium (IM+0.4 M sorbitol) for an h. Then, they were transferred to medium MICE1 containing 1 mg/L ammonium glufosinate for 4 wk (with sub-cultures every 15 d). Normal calli were transferred to shoot induction

media (MRV1) and incubated at 28°C in a culture chamber with a photoperiod of 16-h light/d. After 40 d, calli with shoots longer than 5 cm were transferred to flasks containing rooting medium (MEEV3) and incubated at 28°C in a culture chamber with a photoperiod of 16-h light/d. Finally, seedlings showing good development were washed with distilled water to eliminate the remnants of the culture media, transferred to pots with a 1:1 soil/vermiculite mix, and maintained isolated in high humidity conditions in a growth chamber.

Molecular analysis. Plant genomic DNA was extracted from leaf tissue (3 g) of rooted plantlets using the protocol published by Lipp *et al.* (1999) for polymerase chain reaction (PCR) analyses. The presence of *egfp* transgene was tested in PCR assays using the primers 5'-GGGGACAGCTTCTTG TACAAAGTGGGGATGGTGAGCAAGGGCGAGGAGC T-3' and 5'-GGGGACAACCTTTGTATAAAGTTGGTTAC TTGTACAGCTCGTCCATGCC-3'. The presence of the *bar* gene was determined in PCR assays using the primers 5'-GAGGCACAGGGCTTCAAGAG-3' and 5'-AAACCCAC GTCATGCCAGTT-3'. PCR amplifications were carried out in 25 µL final volumes containing 1 × Taq polymerase reaction buffer (Promega, Madison, WI), 1.5 mM MgCl₂, 0.2 mM dNTPs, 0.2 mM of each primer, and 1 U GoTaq® polymerase (Promega). The PCR cycles consisted of an initial denaturation step of 94°C for 5 min, followed by 35 cycles of 94°C for 30 s, 58 and 60°C for 1 min for *egfp* and *bar*, respectively, 72°C for 30 s, and a final extension of 72°C for 10 min. The technique described in Ortiz *et al.* (1997) was used for genomic DNA blot analysis. Briefly, genomic DNA was extracted from 6 g of young leaves using the CTAB method (Saghai-Maroo *et al.* 1984). Genomic DNA (30 µg) was digested with restriction enzymes (*Eco*RI and *Pst*I), electrophoresed overnight at 25 V in 1% (*m/v*) agarose (1 × TAE) gels, and blotted onto nylon membranes (Hybond N, Amersham, Pittsburgh, PA) using 10 × SSC buffer. DNA was UV-fixed with a UV transilluminator for 3 min and then by baking at 80°C for 2 h. Probes were PCR-labeled in a 100 µL reaction, containing 5 ng of plasmid DNA, 15% glycerol, 1 × Taq buffer (Promega), 1.5 mM MgCl₂, 50 mM of each dNTP, 0.2 mM oligonucleotides, 5% dig-dUTP, and 1 U of Taq polymerase (Promega). Non-radioactive hybridization and detection procedures were performed according to Boehringer-Mannheim instructions (Dig Luminescent Detection Kit; Mannheim, Germany) using CSPD as a chemiluminescent substrate. Hybridized membranes were exposed to films Hyperfilm-ECL (Amersham) for 2–12 h.

In vivo assay for tolerance to ammonium glufosinate. In order to set up an *in vivo* assay for the tolerance to ammonium glufosinate, the mean lethal dose (LD₅₀) of this selective agent was determined using the genotype Q4117. Petri dishes containing 4 cm sections of young leaves, and 5 mL of

ammonium glufosinate solution were placed in a growth chamber at 28°C with a photoperiod of 16-h light/d for 15 d. The different concentrations of ammonium glufosinate applied to the leaf sections were 0.0, 0.5, 1.0, 1.5, 2.5, 5.0, and 7.5 mg/L. The results were analyzed using the *drc* (*dose-response curve*) package for the R software (Ritz and Streibig 2005). The effective dose (ED), at a specific 50% response level (ED₅₀), can be determined through a variety of data analysis methods. In this case, we used a log-logistic model (Ritz and Streibig 2005) with two parameters (lim upper=1 and lim lower=0) given by the following equation:

$$Y = 1 / (1 + \exp[b(\log x - \log e)])$$

where *e* is the ED₅₀ and *b* denotes the relative slope around *e*. An F-test for lack of fit was done to confirm the statistical model fit. The variable reported was leaf necrosis after 2 wk of treatment. Putative transgenic and control plants were tested for *in vivo* tolerance to ammonium glufosinate using the minimal lethal dose as described above. Kruskal–Wallis test was done using the *agricolae* package for the R software (Mendiburu 2013).

Results

Plant regeneration. We designed alternative protocols based on the information reported by Grando *et al.* (2002) and Gondo *et al.* (2005). A total of 2,811 mature seeds originating from Q4117 (apomictic) and 279 mature seeds from the cross Q4188 (sexual) × JS-83 (sexual) were successfully processed. A lower number of seeds originating from the sexual genotype Q4188 was due to the limited availability of seeds. On average, the seed set of this genotype in cross-pollination was only about 27% (Acuña *et al.* 2007). The procedure used to sterilize the seeds was highly effective, since contamination was low (2.3%). After 5–7 d of culture in MM5 medium, tiny white sprouts were observed emerging from the seeds (Fig. 1a). Formation of callus was observed in the central region of the sprouts. Approximately 4 wk later, they had already reached 15 mm in size and turned yellow-brown (Fig. 1c–d). The results related to callus formation from mature seeds have been summarized in Table 2.

The calli originating from genotype Q4117 were cultured on two different shoot regeneration media (MRV1 and MRV2) differing in CuSO₄ content, in two different incubation conditions (darkness or a photoperiod of 16-h light/d). The calli cultured on MRV1 in the dark underwent considerable growth; regeneration started 2–3 wk after incubation, and several shoots were obtained from the same callus. When transferred to MEEV1 medium, most shoots turned green (Fig. 1e). Better results were obtained by combining MRV1

Figure 1. Plant regeneration from different explants of bahiagrass. (a) Brownish swollen sprouts and early calli formation. (b) Meristem sections cultured on MM2 medium containing 30 μ M dicamba and 5 μ M BA for 25 d. (c, d) Callus produced from a seed explant 4–5 wk after

culture initiation. (e, f) Regenerated green and albino shoots, respectively. (g) Regenerated plantlets with well-developed shoot and root systems growing in soil.

medium and incubation with a photoperiod of 16-h light/d. Shoots were observed emerging from calli after 3–5 wk, most of which were green, but some (6 out of a total of 43 shoots = 14.3%; Table 2) were albino (Fig. 1f). When calli were incubated in MRV2 medium, no regeneration was observed in any of the illumination conditions. Since the number of available seeds originating from sexual genotypes Q4188 \times JS-83 was low, only the best combination for the apomictic seeds was assayed (MRV1 and incubation with a photoperiod of 16-h light/d). Calli originating from Q4188 \times JS-83 showed a similar behavior to those originating from Q4117, but the process was faster (emerging shoots were observed after 2 wk).

After incubation in shoot regeneration medium, calli with shoots were transferred to rooting medium. Shoots originating from the apomictic genotype Q4117 were cultured in two different media: MEEV1 and MEEV2. After 1 wk, considerable elongation of the shoots and the onset of root formation were observed in the regions where calli were in contact with the culture medium. Seeds originating from the sexual genotype were assayed using only MEEV2 medium. After 4–6 wk, the seedlings had reached a considerable size and were able to be transferred to soil (Fig. 1g). No morphological alterations

were observed in plants subjected to *in vitro* culture with respect to controls.

Calli induction data originating from the apomictic (Q4117, ten sets of seeds) and the sexual (Q4188, three sets of seeds) genotypes were compared to evaluate the effect of genotype on callus induction. A highly significant difference in behavior was detected between the genotypes. Calculations were done using percentages based on the number of seeds that produced calli. The percentage of callus induction with respect to the total seeds used was significantly higher in the sexual genotype ($P=0.018$; Table 2). Similar results have been observed for several grass species, including *P. notatum* (Smith *et al.* 2002; Molinari *et al.* 2003; Salehi and Khosh-Khui 2005; Glowacka *et al.* 2010).

Isolated mature embryos were cultured in different media (MM5, MICE1, MICE2, and MICE3; Table 1) to evaluate the effect of PGRs and their concentrations on callus development. Callus formation was observed after 10–15 d of culture in all assayed media. Two types of calli were obtained: (1) compact, nodular, white-yellow, and potentially embryogenic and (2) friable, soft, and translucent. The type and quantity of calli varied depending on the growth regulator composition.

The best results were obtained in medium MICE2 with 35.2% regeneration efficiency (Table 3).

Meristematic regions of vegetative tillers derived from seedlings (Fig. 1b) were excised and spread on six different callus induction media, MM1 to MM6 (Table 1), as described in “Materials and Methods”. Percentages of callus induction and shoot regeneration are shown in Fig. 2 and Table 4. After 20–25 d, calli with shoots longer than 5 cm were transferred to rooting medium (MEEV3). All of these calli developed roots, and those cultured on MM2, MM5, and MM6 media developed more rapidly. Statistical analyses indicated that the MM2 and MM5 media were the most suitable for callus induction from meristems ($P=3.18e^{-06}$).

A second experiment aimed to determine the regions of the meristems that were effective for callus induction. Meristems were collected from seedlings and divided into three sections of the same size: apical, central, and basal. Callus induction results using these different explants are shown in Table 4. Calli formed on MM2 medium regenerated plants more rapidly than those formed on MM5. Regeneration was observed only from calli originating from the central meristematic sections. Regenerated lines originating on MM2 were maintained indefinitely in IM medium and were used to produce second-generation meristems to re-initiate an *in vitro* culture cycle.

Analysis of sensibility to ammonium glufosinate. The effect of ammonium glufosinate on the regeneration capacity of *P. notatum* explants was analyzed using mature seeds from genotype Q4117. An analysis of sensibility was performed according to the protocol described in “Materials and Methods”. Shoots and roots were produced only when selection was applied during the calli sub-culture but not during regeneration. Based on the frequencies of regenerated plants over the total calli subjected to selection, the best selective pressure was 1.0 mg/L ammonium glufosinate. This concentration of selective agent both increased the possibility of recovering transgenic plants and minimized the quantity of plants that escaped selection (escapes). These results validated the use of ammonium glufosinate as a robust and effective selection method.

Gene delivery. Three-week-old calli originating from mature seeds of genotype Q4117 were used for bombardment. The vectors used for transient reporter gene expression assay were the plasmids pDP687 (Ludwig *et al.* 1990) and pAct1-gfbsd2 (Ochiai-Fukuda *et al.* 2006). A total of 140 calli (ten calli per plate, 14 plates) were bombarded once using three alternative compressed helium-generated alternative pressures (600, 800, and 1,100 psi), at a microprojectile flight distance of 5 cm. The highest pressure rendered the best results (145 transformed cells per plate). The transient reporter gene expression assay results are summarized in Table 5. After bombardment, calli were subjected to *in vitro* culture procedures to evaluate their

Table 3. Regeneration efficiency of calli originating from *P. notatum* mature embryos

regeneration capacity. Their behavior in regeneration media (MRV1 and MEEV1) was similar to that observed for non-transformed calli.

Stable transformation of genotype Q4117 was performed on calli produced using the optimized protocol described for mature seeds, followed by post-bombardment selection with 1.0 mg/L ammonium glufosinate. Six experiments involving ten plaques containing ten calli each (600 calli in total) were carried out (Table 5). Calli were bombarded with equal amounts of the plasmids pAct1-gfbsd2 (Ochiai-Fukuda *et al.* 2006) and pBS86-46 (Pact1D:cgf-s:rga2i:cgf-as:T35s/Pubi:bar:Tnos; Thompson *et al.* 1987), in order to achieve co-transformation (Fig. 3a–i).

Seventy-five putative transgenic plants recovered from the selection step were rusticated. A set of 42 plants was selected at random to check for the presence of the transgenes. *Bar* and/or *egfp* genes were detected by PCR in 27 plants (64.2% transformation efficiency), with 22 plants (52.3%) and 16 plants (38.0%) of the transgenic plants containing *egfp* and *bar*, respectively. Eleven of the 27 transgenic plants contained both transgenes, resulting in a 40.7% co-transformation frequency (Fig. 3k, l). Genomic DNA blot analysis was undertaken for four plants (Fig. 3m). The *egfp* transgene was stably expressed in all main organs including leaves, stems, and

roots. Fluorescence was detected in meristematic tissues, like root tips. *Egfp* expression was also observed in ovaries and pollen grains (Fig. 3n, p). The transgenic plants were phenotypically normal and able to produce seeds.

In vivo assay for tolerance to ammonium glufosinate. An ED is defined as the dose of an agent that produces a specific effect in a defined fraction of the individuals under analysis. The "mean effective dose" (ED₅₀) is the dose that produces a quantal effect in 50% of the individuals. The ED₅₀ is commonly used as a measure of reasonable expectance of a drug effect. *In vitro* assays with different concentration of ammonium glufosinate showed that the estimated parameters were $b = -1.76644$ and $e = 0.72 \pm 0.10$ mg/L. A goodness-of-fit test corroborated that the data fitted to the selected model (P -value = 0.7998). Accordingly, 1.0 mg/L was the closest concentration to the ED₅₀ (0.7 mg/L) determined by the model, we used this concentration to compare the experimental plants versus wild type. Assays were carried out on plants T-51 (*egfp*+, *bar*-), T-57 (*egfp*+, *bar*-), T-29 (*egfp*+, *bar*+), and T-65 (*egfp*+, *bar*+). The results showed that plants T-29 and T-65 were significantly resistant to the ammonium glufosinate treatment, whereas plants T-51 and T-57 behaved as the wild type (Fig. 3j).

Figure 2. Percentages of calli and shoot regeneration obtained in six different media. Data are presented as mean±standard deviation ($n=7-5$). Means sharing different letters denote statistically significant differences at $P<0.05$.

Table 4. Regeneration efficiency of calli originating from shoot meristem sections

Discussion

In this work, we report the production of morphologically normal transgenic plants of the apomictic, tetraploid bahiagrass (genotype Q4117) after particle bombardment using an efficient regeneration system. The *in vitro* culture and plant transformation protocols used here were adapted from previous works published by Bovo and Mroginski (1989), Grando *et al.* (2002), Smith *et al.* (2002), and Gondo *et al.* (2005).

Success rate in the selection of putative transformed plants is mainly dependent upon the dose rate of selective agents. Their concentrations need to be carefully chosen to avoid either being too low and thereby allowing undesirable numbers of escapes to develop, or too high so that transformed plants expressing moderated levels of resistance are lost (Ijaz *et al.* 2012). It is a well-known fact that sensitivity to selective agents shows high dependence against genotype in monocots (Ijaz *et al.* 2012). Here, a *P. notatum* genotype that had not been transformed previously (Q4117) was tested using ammonium glufosinate. Selection curves indicated that a dose of 1.0 mg/L of ammonium glufosinate (accepting around 10% of escapes in the transformation experiments) should be used in order to detect even those events with low transgene expression, with a minimal number of escapes. Smith *et al.* (2002) used a higher optimum glufosinate dose (3.0 mg/L) for their *P. notatum* transformation experiments, probably due to the use of another target genotype in combination with the selection of a different threshold for tolerance of escapes. However, both transgenic plants (with *bar*) and non-transgenic plants (without *bar*) developed strong and stable resistance to

ammonium glufosinate during selection (only 32 transgenic plants were identified from 674 glufosinate-resistant plants; transgenic plants recovery among selected plants=4.7%; Smith *et al.* 2002). A wide emergence of stable resistance to glufosinate and the consequent reduction of the selection efficiency were not observed for the *P. notatum* genotype used here (Q4117). In our experiments, 16 transgenic plants containing *bar* were identified among 42 total selected plants (transgenic plants recovery among selected plants=38%).

A new meristem-based *in vitro* culture procedure adapted from Bajaj *et al.* (2006) was introduced, which can be implemented to increase somaclonal variation, a desirable goal pursued in breeding strategies for clonally reproducing grasses. Another advantage of this protocol is that it demands a shorter period of tissue culture. This feature has been previously emphasized in other monocot transformation reports (Altpeter *et al.* 1996; Zhang *et al.* 2003; Gao *et al.* 2006).

Twenty-seven independent transgenic lines were regenerated following biolistic gene transfer of 600 calli. The transformation efficiency (8.0%) calculated based on the bombarded calli was higher than the values 2.2% (Gondo *et al.* 2005), 1.5–4.0% (Altpeter and James 2005), 1.3% (Agharkar *et al.* 2007), and 1.6% (James *et al.* 2008) reported for bahiagrass. However, the efficiency of our system was lower than the 10% showed for *P. notatum* cv. 'Argentine' (Sandhu *et al.* 2007; Sandhu and Altpeter 2008). Genotypic differences and alterations in tissue culture and selection protocols may have contributed to this discrepancy.

Co-transformation allows multiple gene transfer to plants. This strategy is necessary for stacking of transgenes, the expression of different polypeptides forming a multimeric

Table 5. Gene delivery

protein, the introduction of several enzymes acting in a metabolic pathway or the expression of a target protein and the enzymes required for specific types of post-translational modification (Altpeter *et al.* 2005). The co-transformation frequency (40.7%) obtained using our protocol is lower than the values of 50–60% reported by Zhao *et al.* (2007) and of 81% by Kumar *et al.* (2010). These authors adopted similar bombardment strategies employing high molar ratios of the constructs used for co-transformation, whereas we used equal amounts of the plasmids pAct1-gfbsd2 and pBS86-46. Even so, our co-transformation efficiency is acceptable for practical applications.

Marker-free transgenic plants are a desirable target for commercial use. There are several strategies to exclude selectable marker genes from transgenic plants, such as co-transformation (Kumar *et al.* 2010), site-specific recombination (Gleave *et al.* 1999), multi-auto-transformation vectors (Ebinuma *et al.* 1997), transposition (Goldsbrough *et al.* 1993), homologous recombination (Zubko *et al.* 2000), genetic programming (Verweire *et al.* 2007), and use of alternative selection markers (Erikson *et al.* 2004). Nevertheless, concerns about selectable marker genes have to be addressed differently in apomictic species. Our results suggest that it is possible to obtain transgenic bahiagrass in co-transformation experiments with the gene of interest but without the selectable marker: 11 transgenic plants containing only *egfp* were obtained from 600 calli bombarded (1.8%). Even though the transformation frequency was low, it may provide a reliable tool for generating transgenic apomictic plants for commercial use.

In the last few years, dozens of genes differentially expressed in apomictic and sexual developmental pathways have been isolated by several research groups from genetically poorly characterized apomictic species (Rodrigues *et al.* 2003; Albertini *et al.* 2004; Cervigni *et al.* 2008; Laspina *et al.* 2008; Yamada-Akiyama *et al.* 2009; Polegri *et al.* 2010). Some of these are protein-coding genes, which facilitated the identification of orthologs in model species and the analysis of mutant genotypes to predict their function. However, a considerable number of the identified candidates correspond to non-characterized hypothetical proteins and putative retrotransposons, miRNAs, and novel RNAs. Therefore, functional analyses of these candidate genes require the generation of mutant or transformed genotypes of the apomictic species originally used to isolate those genes. Some candidates were underrepresented in the reproductive tissues of apomictic plants with respect to sexual ones. Repression or silencing of these candidates in sexual plants and activation in apomictic plants could reveal their potential roles in reproductive development. Conversely, genes naturally over-expressed in the reproductive tissues of apomictic plants with respect to sexual ones need to be artificially upregulated in sexual plants and silenced in apomictic ones to investigate their activity. Therefore, functional analyses of these genes possibly associated with apomixis require a robust method to produce transgenic

plants from both sexual and apomictic tetraploid genotypes, since apomixis expression occurs only at polyploid levels.

A biolistic platform appears to be one of the best ways to obtain large sets of transformed plants to characterize genes related to apomictic development. Here, we present several alternative protocols, starting from a variety of explants, which can be used to obtain transformed plants of tetraploid *P. notatum*. Even though all tissues proved to be suitable to generate calli and regenerated plants, we selected mature seeds as the explant of choice because of the simplicity of the technique involved. However, in the absence or shortage of seeds, the meristem-based protocol assayed here could be extremely useful. Since sexual tetraploid plants are artificial and exhibit a low seed set (Acuña *et al.* 2007), a meristem-based protocol also represents an excellent opportunity to produce transgenic plants from this particular plant material. Moreover, when the objective is to achieve somaclonal variation (for example, in breeding programs aimed at introducing variation into clonal apomictic genotypes through tissue culture), the application of a serial meristem-based *in vitro* culture protocol would be most convenient.

Acknowledgments Thanks are due to Prof. Camilo Quarín for donating the plant material used in this work. We also thank Prof. German Spangenberg for kindly providing the destination vector employed to construct the plasmid pSB86-46 used for the stable transformation experiments. We thank Dr. Gabriela Breccia for her valuable advice on statistical analyses. This work was supported by: Agencia Nacional de Promoción Científica y Tecnológica (ANPCyT), Ministerio de Ciencia y Tecnología, Argentina, PICT 2007-00476, PICT 2011-1269 and PME-2006-03083; Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Argentina, PIP 11220090100613; Universidad Nacional de Rosario, proyecto 19G/253. M. Mancini, N. Weitovich, M. Podio and L. Siena received fellowships from CONICET (Consejo Nacional de Investigaciones Científicas y Técnicas, Argentina). J.P.A. Ortiz, S.C. Pessino, and S.A. Felitti are career members of CONICET.

Conflict of interest The authors declare that they have no conflict of interest.
